Nelumbiem

Sept 22nd 1860

Some of the largest tubers were cooked. Boiled as well as baked they were not as soon done as potatoes & required a longer time. nevertheless they remained firm and kept their shape perfectly well. Inside they looked reddish. Baked they were much better than boiled and had a mealy and sweet taste considerably resembling sweet potatoes, & very pleasant having nothing of the stagnant water taste about them.

Sept 30th My investigations about the manner of growth of Nelumbium are now nearly closed. It grows with astonishing regularity, and all the parts can be seen in the bud (smallest) even the flower, though it may never become developed.

The decomposition of the tubers becomes gray and at last black, while the stem turns into a most beautiful violet colour, and the tubes are filled with gaseous filaments; the odor is very fetid considerably resembling rotten potatoes. The purple colour appears to emanate from deep purple globules which form in the cells, considerably larger than the starch and only one apparently in one cell

Nov. 1860

Enveloping sheath is penetrated on its back, and remains entire on the upper part or bursts finally in two halves.

If entire it remains between the stipule and the leaf! see tab 44 & 45.

The stipule is penetrated by the branch and usually, bears in two halves,

the inner basal back of sheath is of ~~the~~ divided in two halves, but not penetrated.

* (see below) Melambium.

The node is considerable thicker than the internode, and somewhat globose. It is not penetrated by the tubes, but contains between the twisted Cigaceous fibres often small irregular cavities, connected with the tubes

The roots spring from a belt, the lowest or hindmost part of the node, which is interrupted above and below, forming 2 half belts, which are sometimes again slightly interrupted.

The roots are thick fibres, white, with short simple lateral fibres; they originate from the Cigaceous tissue and pierce through the thick cellular parts; before they pierce, they are indicated by protuberances

* (see above) The petiole has tubes quite similar to the branches, 4 larger lateral ones, those towards the back being the largest, and 2 quite small ones on the back, and usually a small one + point and one on each side between the large ones, with or mostly without a central one.

The next organ, after the belt of roots is the enveloping sheat

Velumbium.

Nelumbo nucifera — structure of stem 1

Oct 6 800

The stem of the plumula is erect, and has 7 tubes; the pair on the side of the (first) lowest leaf (and towards the periphery of the stem and the funiculus) the odd one to the opposite side, at the second leaf.

The growing stem has from 6—9 tubes besides the central one.

In the smallest stem the 6 tubes are so arranged that the 2 smallest pairs are placed on the upper side, the largest pair on the sides and the middle tipped pair on the lower side

(the tubes of the petiole are arranged exactly so, the back or portion corresponding with the upper side)

In larger stems the six tubes already mentioned are more equal but a seventh is introduced at the lowest side, between the lowest pair, usually wedge shaped.

In still larger ones an 8th very small one is added above

and in the flower bearing ones a second small one is added to the first one showing a pair of small tubes above.

(Tubers are constructed similarly only the tubes (usually 8 or 9 and a central one) are small, compressed, twisted.)

The first bract (e) is opposite to the pair of small tubes.

While the lowest leaf of plumula is on the same side where they would be

The branches have an arrangement of tubes opposite to that of the stem.

Octob 1860

Nelumbium, structure of stem. 2.

The lowest branch is the scape or peduncle it has besides the central and a number of smaller ones, 8 to 9 regular tubes, usually with a pair (sometimes with a single one) small ones, on the side opposite to the bract, & the axills of which bears it and opposite to the arrangement of the stem tubes.

The lowest sepal of this flower-branch is opposite to the floriferous bract, therefore on the side of the small tubes.

The second branch born on the same side in the axil of the leaf has always 6 tubes, the smallest pair on the lower side opposite to the leaf in the axil of which it rises, and also opposite to the arrangement of the stem tubes.

The lowest bracts of the branch both on the same side are (equally as the lowest sepal) opposite to the proliferous leaf, therefore on the side of the smallest tubes.

The flowering branch or scape or peduncle becoming erect grows up with no twist or a very slight one

The leaf bearing branch however being destined to grow horizontally twists where it grows in soft mud so that the pair of small tubes and consequently the flowerbearing bract and the branch bearing leaf come from the now upper side and the whole has the arrangement of the stem itself.

Where the mud is too hard, the twist can not take place, as it seems; and in that case, the leaf and bract and ramification of stem (terminal bud) are curved from the lower side upwards.

The continuation of the stem itself is exactly like the older part, even continuing some odd shaped or some accessory tube where the previous joint is fully matured. or where this is young, & contains fewer tubes, more tubes are gradually added, or those already present enlarged and more fully developed.

During spring and summer the stem grow elongated or more or less expanded but towards fall the latest growth forms shorter and thicker tuberous stems, filled with Amylon, which with their buds are (probably) all that lives through winter and continues the plant in the following spring.

To the long internode of stem, which at its upper end bears the rootlets follows 2 short and crowded internodes bearing 1 with ventral enveloping bract, 2 with dorsal, flower bearing and leaf enveloping bract, and 3 with leaf itself (the branch bearing stipulated leaf) at the anterior end of the long internode. (one and) a complete repetition of the same system.

The leaf-branch has at its base, opposite to the branch-bearing leaf, two bracts, one above the other, the lower outer one notched or bifid, the inner one larger, entire but usually at last splitting in two.—

Dr E.

Morphology of Nelumbium luteum

Dr E. resumed and concluded his remarks on Nelumbium luteum illustrated by a great many drawings

Dr E. resumed and concluded his remarks on Nelumbium luteum illustrated by a great many drawings (views) of plants, &c

Nelumbium is common in our deep stagnant waters, not only one of our most showy plants, with its large leaves & large flowers, with erect seed vessels & edible tubers but it is also one of the most curiously constructed plants following its peculiar but very simple type with astonishing regularity

and never deviating from them. The morphology has always attracted the attention of botanists & Mr. Trécul has tried to develop its morphological relations giving a long explanation of the plant very attentively & intelligently, but I believe that the simple material at my disposal has permitted me to make some observations which may have escaped my predecessors.

The structure of the seed is well known I will therefore only repeat, that the (large green plumule - lower leaf of the stalk (always directed towards the hilum shaple) has at its base petiole only a narrow sinus surrounding the stalk, which subsequently replacing the stipule of the follow leaf. The stipule of this one embraces the following leaf and the stipule of the third the fourth leaf all of them will form a sheath. When then distinctly arranged leaves have grown a little can developed, the stem very slowly realises in the mud and now begins the mode of vegetation which ever after characterizes the plant. The stem realising on or in the mire of the lakes or ponds one side of course is the upper or dorsal the other the lower (or ventral one), the direction towards the growing part of the stem I shall call the anterior, that towards the older parts, the posterior side. The elongated internode now existing horizontally on the ground is terminated at its anterior end by a bud scale (which has an opposite bract (a) to the leaf two short crowded internodes, the former one with

one with ovule at (b)

dant, preceding it thereon ventral or dorsal down ward, the ~~next~~ ~~one~~ grows in opposite direct. to the last, or upward ~~on~~ ~~back~~ upwards, in the same direction as the preceding leaf; the next above then comes in the same upward direct. the single leaf, (c) with a sheathing stipule at base. The long internode connected with this leaf follows the same direction ~~again~~ and thus we have the simplest organization of the plant, before it arrives at maturity: 2 ranks with scales (with short internodes) in opposite decussation and a leaf in the direct of the last scale, with a long internode. The next part of the root is composed by many fibres, long simple, spun from the base of the last internode, just below or within the lowest scale, in a belt divided by two naked grooves down and below into two halfbelts. —

The flower bearing plant develops its organs

As soon as the plant prepares for propagation in two manners; by forming first buds and by the flowers and fruit, and this also in the most simple as well as most constant manner, a single branch and a single flower, the latter developed out of the axil of the last leaf (ad). The flower is produced from the axil of the scale b, and bears on its top the two lowest organs of the flower, which might be named sepals or bracts the lower one (d) opposite the scale, the anterior, the upper one (e) opposite to the last or posterior. The following very numerous organs of the flower follow more complicated laws of phyllotaxis.

The branch (ram) springs from the axil of the last leaf, and bears at its base two scales (f & g) one above the other, both opposite to the leaf or anterior. to which a long internode succeeds, which at its end recommences the succession of organs of the stem, as detailed before, But it will be seen that the arrangement just explained that so that the scale a is opposite to the last leaf, f & g b and c in the same direct; ~~But it will be seen that~~ has the
